

Charged Cosmic Rays up to the knee region and beyond (III)

Antonella Castellina
Istituto Nazionale di Astrofisica
IFSI, Torino
e-mail: castellina@to.infn.it

Outline of the lecture

Introduction

Origin, acceleration and propagation of cosmic rays

Models of the knee

Extensive Air Showers

Energy spectrum and composition: measurement and results

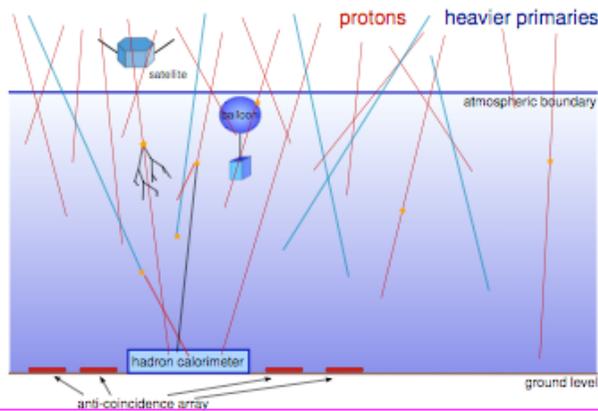

The measurement of the p-Air cross section

Anisotropy studies with EAS arrays

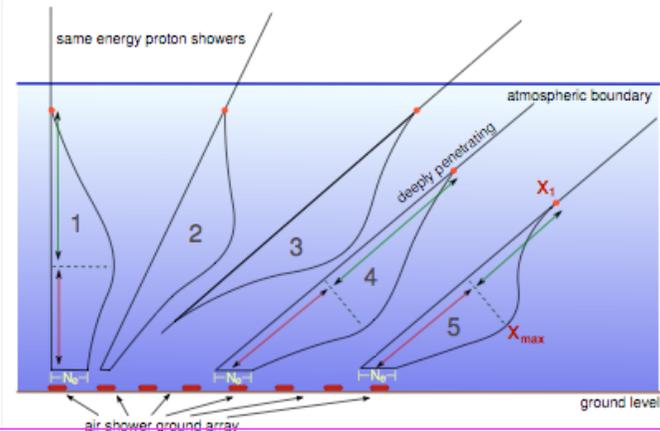

The Galactic to Extragalactic transition

Future projects

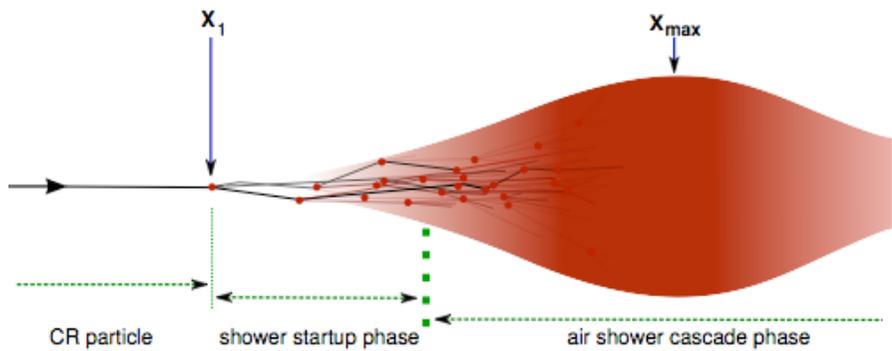

The measurement of σ_{P-Air}

Unaccompanied hadrons
 Measure the unaccompanied hadron flux at 2 different atm depths
 Balloons on top, calorimeters at ground level
 $\Lambda_{att} = (x_{top} - x_{ground}) / \ln(\Phi_{top} - \Phi_{ground})$

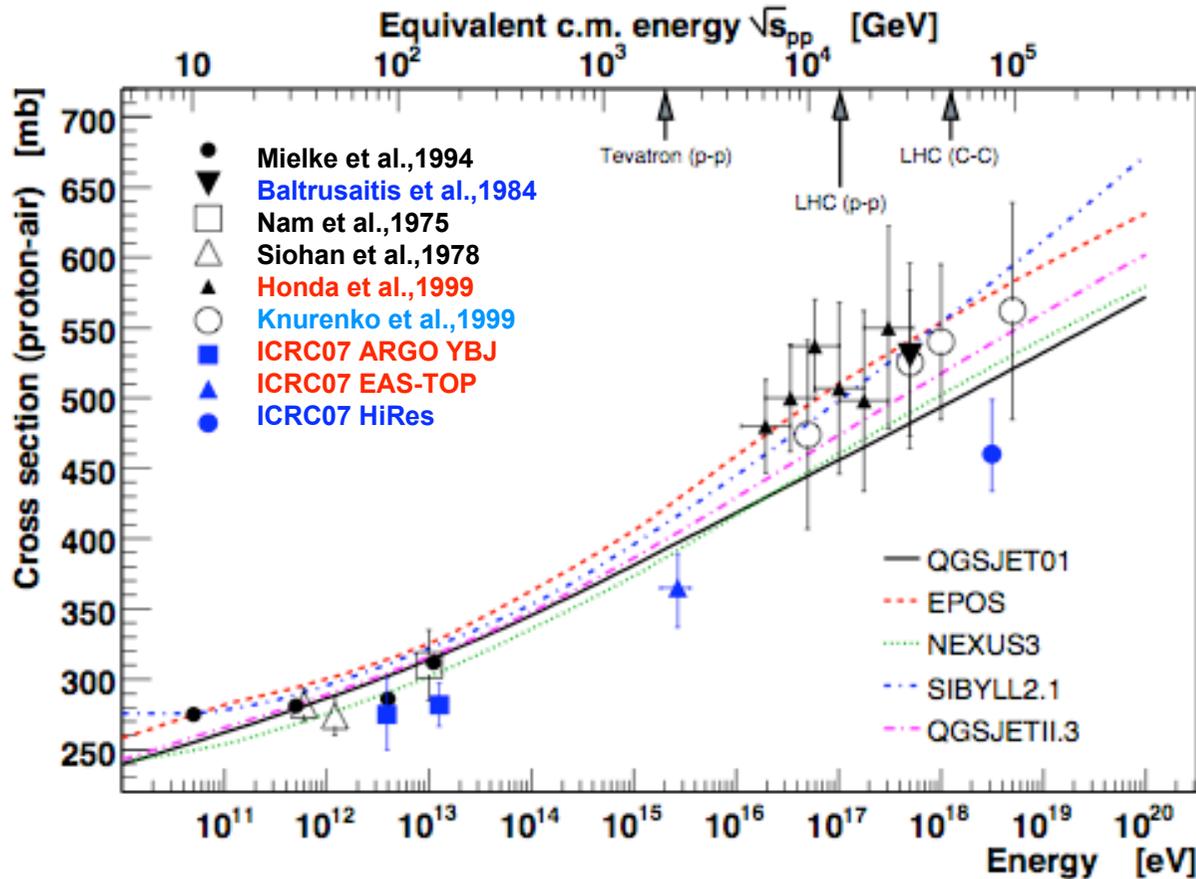

$N_\mu - N_e$ from surface detectors
 Constant N_μ fix E_0
 Constant N_e fix development stage
 $f(\theta) \propto \exp\{-x_0 (\sec \theta - 1) / \Lambda_{obs}\}$
 $\Lambda_{obs} = \lambda_{int} K_{EAS}$

x_{max}
 Directly observed
 $P(x_{max}^{rec}) \propto \exp\{-x_{max}^{rec} / \Lambda_{obs}\}$
 $\Lambda_{obs} = \lambda_{int} K_x$
 smaller fluctuations
 x_{max} shape from fluorescence
 x_{max} fluct from Cerenkov

The measurement of σ_{P-Air}

Unaccompanied hadrons
 $N_\mu - N_e$ from surface detectors
 X_{max} shape from fluorescence
 X_{max} fluct from Cerenkov

$K(N_e N_\mu) \neq K(X_{max})$
 K strongly depends on models
 p/He uncertain

$\Lambda_{abs}^{EXP} > \Lambda_{abs}^{MC}$:
 deeper penetration of EAS in atm
 respect to predictions

Anisotropy from diffusion

Compton-Getting effect

The method and the experimental challenge

The low and high energy region

Hints for the transition region

Anisotropy studies with EAS arrays

T = time for a cosmic ray to reach Earth from its source in straight line
 τ = actual time needed by the cosmic ray

Anisotropy $\delta = \tau / T$

100% anisotropy if $\tau = T$, CR directly to Earth
100% isotropy if $\tau = \infty$, complete isotropization

Any $\delta \neq 0$ implies a motion

Propagation of the CR from the source in the intergalactic space

Motion of the Earth/Sun system in an isotropic gas (e.g. the CR one):
the Compton-Getting effect:

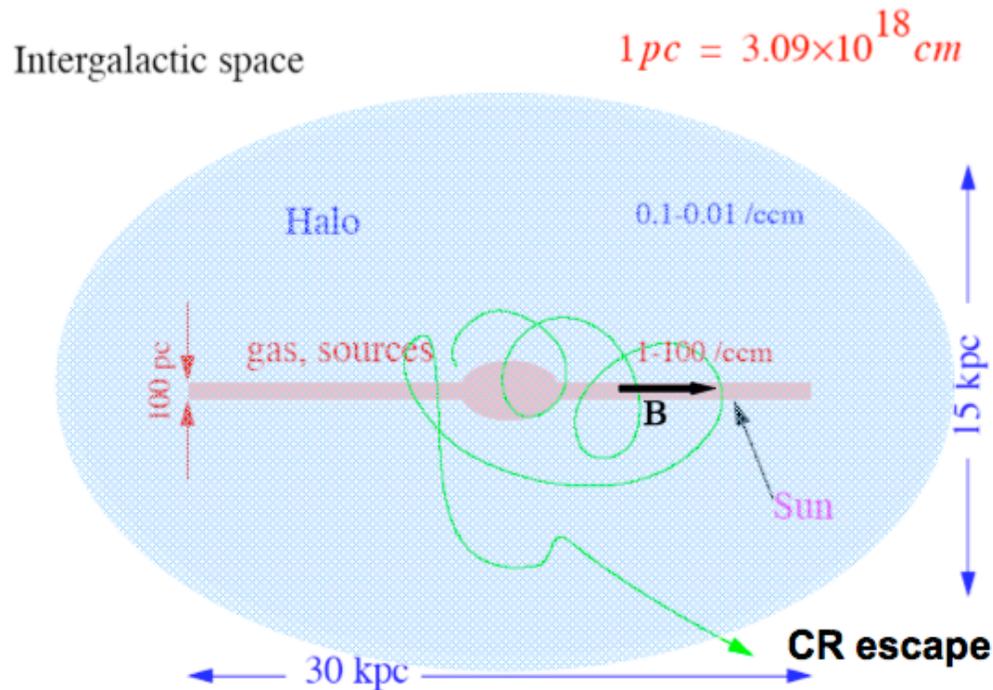

Anisotropy from Diffusion

Cosmic rays propagate in the Galaxy guided by magnetic fields $\vec{B}(\vec{r}) = \vec{B}_{reg}(\vec{r}) + \vec{B}_{turb}(\vec{r})$

They are confined in the Galaxy up to $\sim 10^{18}$ eV, since the curvature in a Galactic magnetic field of $\sim 3 \mu\text{G}$ is

$$r_g[\text{pc}] = \frac{E_{15}[10^{15} \text{ eV}]}{B[\mu\text{G}]Z}$$

(1 EeV proton r_g
 \sim thickness of Galactic disk)

$$D = \frac{1}{3} \lambda_D v$$

diffusion coefficient

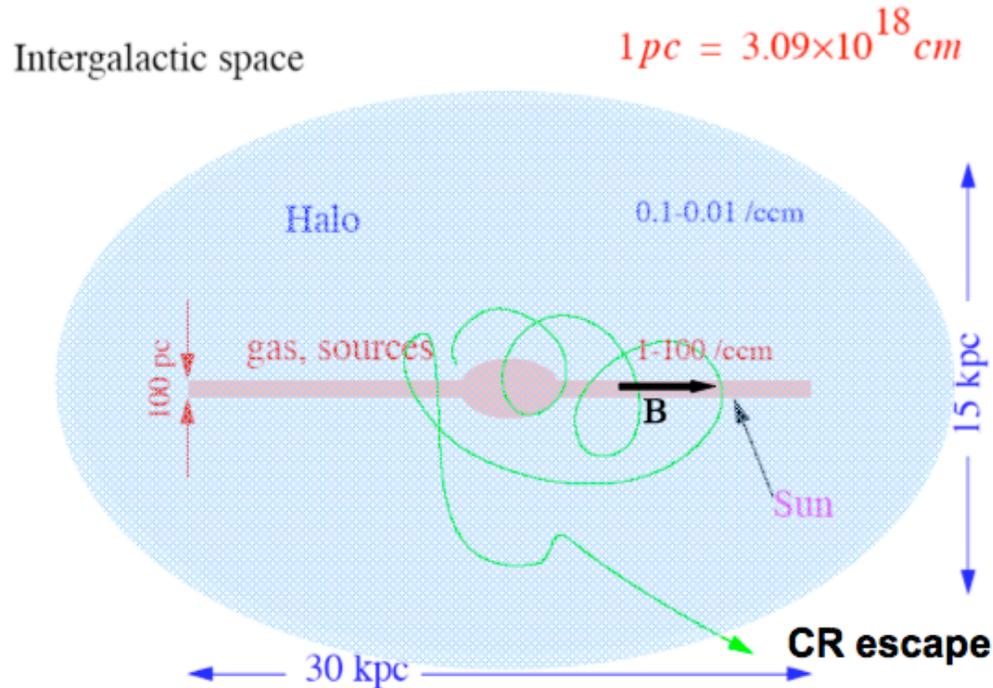

$\lambda_D =$ diffusion mean free path \sim
 scale of ISM inhomogeneities
 (0.1-0.3 pc)

$$\delta = \lambda_D \frac{\partial N}{\partial x} \frac{1}{N} = \frac{3D}{v} \left| \frac{\nabla N}{N} \right|$$

If diffusion is present, density gradients appear, since CRs flow away from the Galactic plane, and there is anisotropy

$$\lambda_{esc} = \rho v h H / D = \rho v h / v_D = \rho v \tau_{esc} \propto R^{-m} = (E/Z)^m$$

v = particle velocity
 ρ = disk density = $1/\text{cm}^3$
 H = halo scale height $\sim 700 \text{ pc}$
 $D/H = v_D$ = escape velocity $\sim 1.5 \cdot 10^6 \text{ cm/s}$
 $D \sim 10^{28} \text{ cm}^2/\text{s}$

D increases with E ,
 hence δ increases with E
 $\delta \sim v_D/v \sim 10^{-4}$
 level of expected anisotropy

Compton-Getting effect

Motion of Earth and Solar System in an isotropic gas in the rest frame

Earth orbiting around the Sun (in solar time):

expected

$$\frac{\Delta I}{\langle I \rangle} = (\gamma + 2) \frac{v}{c} \cos \vartheta$$

measured

$$\frac{\Delta I}{\langle I \rangle} \sim 0.047\%$$

galactic CR anisotropy

Solar System moving through the cosmic rays "gas" (in sidereal time)
galactic CR anisotropy

Solar System moving with $v \sim 350$ km/s through the CMB rest frame

extragalactic CR anisotropy

$$\frac{\Delta I}{\langle I \rangle} \text{ (exp) } \sim 0.6\% \cdot \vartheta$$

At Earth:

I = CR intensity

γ = slope ~ 2.7

$v_{\text{det}} \sim 30$ km/s

θ = Angle between the detector motion and the CR arrival direction

Anisotropy studies with EAS arrays

EAS arrays have

uniform exposure in right ascension α (due to Earth rotation),
not uniform exposure in declination δ : $\Delta\delta = f(\text{array geographical position, zenith angle dependence of the shower detection and reconstruction})$

Method: analysis in α , through the harmonic analysis of the counting rate within a defined δ band [formalism of Rayleigh]

amplitude A $A = \delta \cos d$ (d = declination of observation)
phase Φ (hour angle of the maximum intensity)
probability P to detect a spurious amplitude

Experimental challenge:

- expected amplitudes very small ($10^{-3} - 10^{-4}$)
need long term observations and large collecting areas
- spurious effects have to be kept as small as possible
need area uniformity and time stability, continuity of operation
- dependence on pressure and temperature
Many consistency checks are needed

Anisotropy studies with EAS arrays

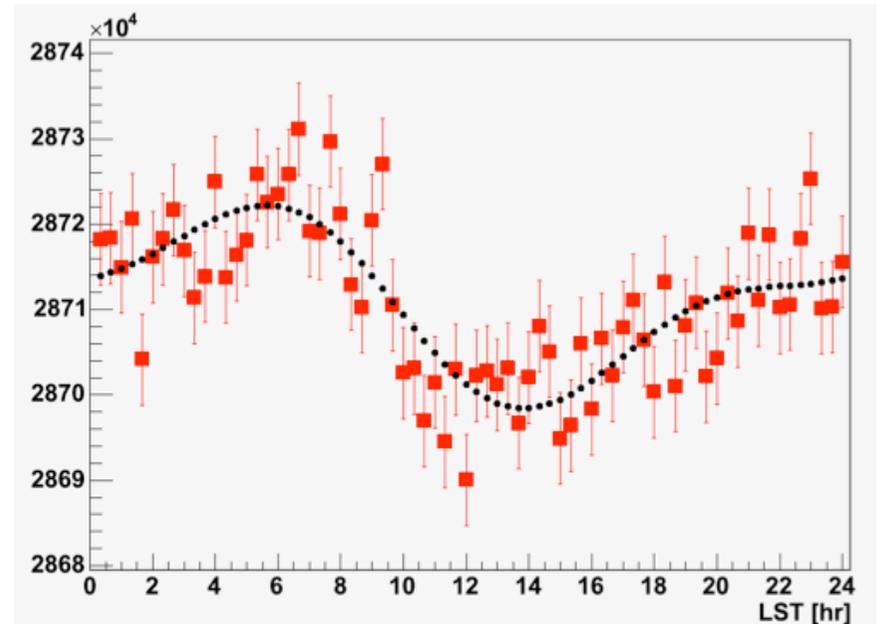

Experimental challenge:

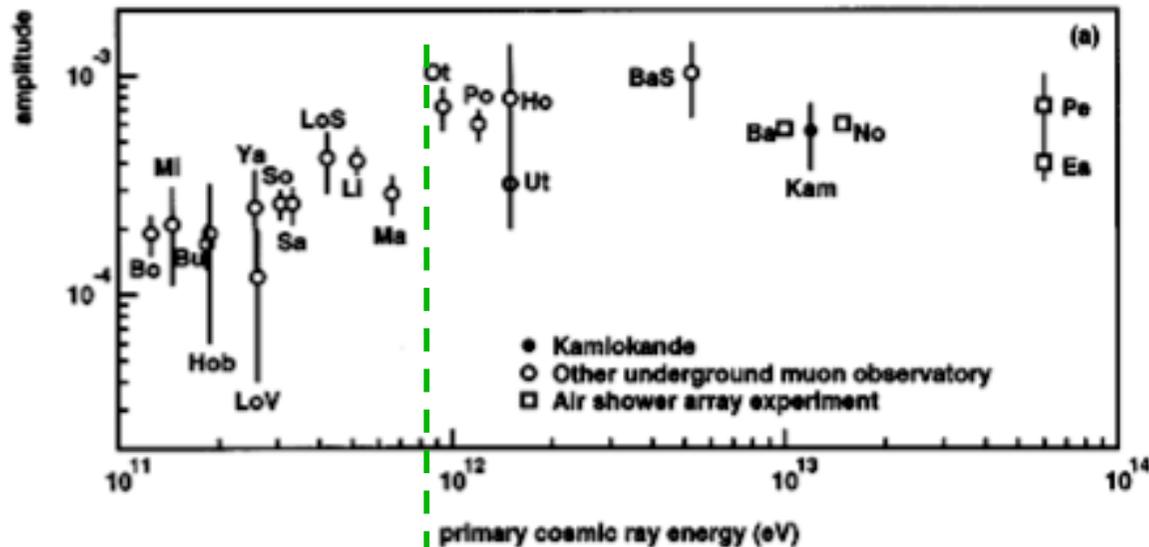

- expected amplitudes very small ($10^{-3} - 10^{-4}$)
need long term observations and large collecting areas
- spurious effects have to be kept as small as possible
need area uniformity and time stability, continuity of operation
- dependence on pressure and temperature

Many consistency checks are needed

Experimental method:

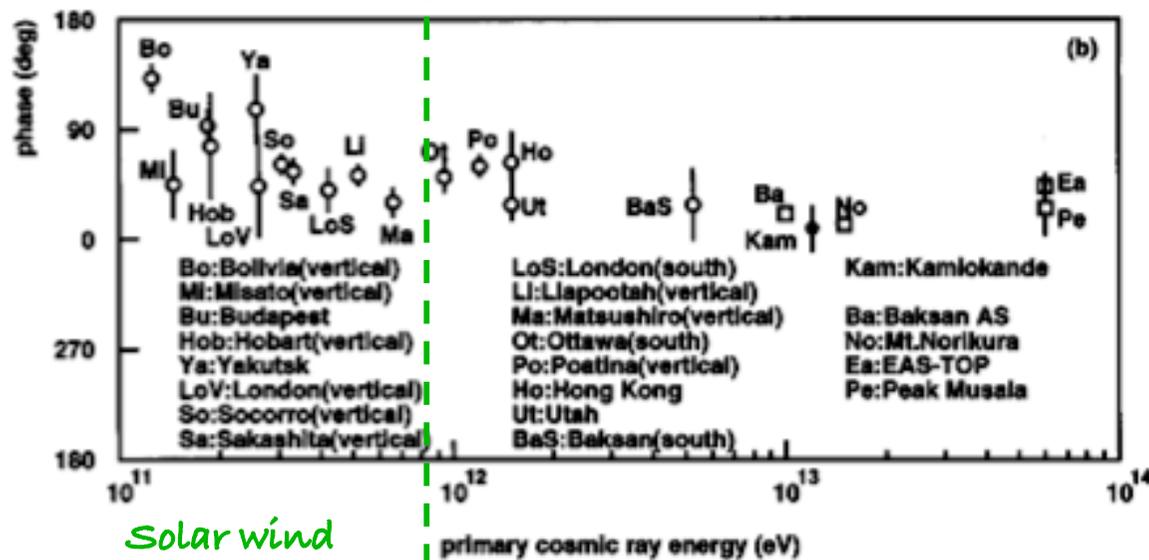

- ✓ For each EAS :
arrival time and direction, α and δ , E
- ✓ Correct the counting rates for P,T
- ✓ Apply some safety cuts
- ✓ Make consistency checks
(antisidereal time distribution,
Compton-Getting effect, etc.)

The "low" energy range

The measurements are made underground or with high altitude detectors below 10 TeV and with EAS arrays above

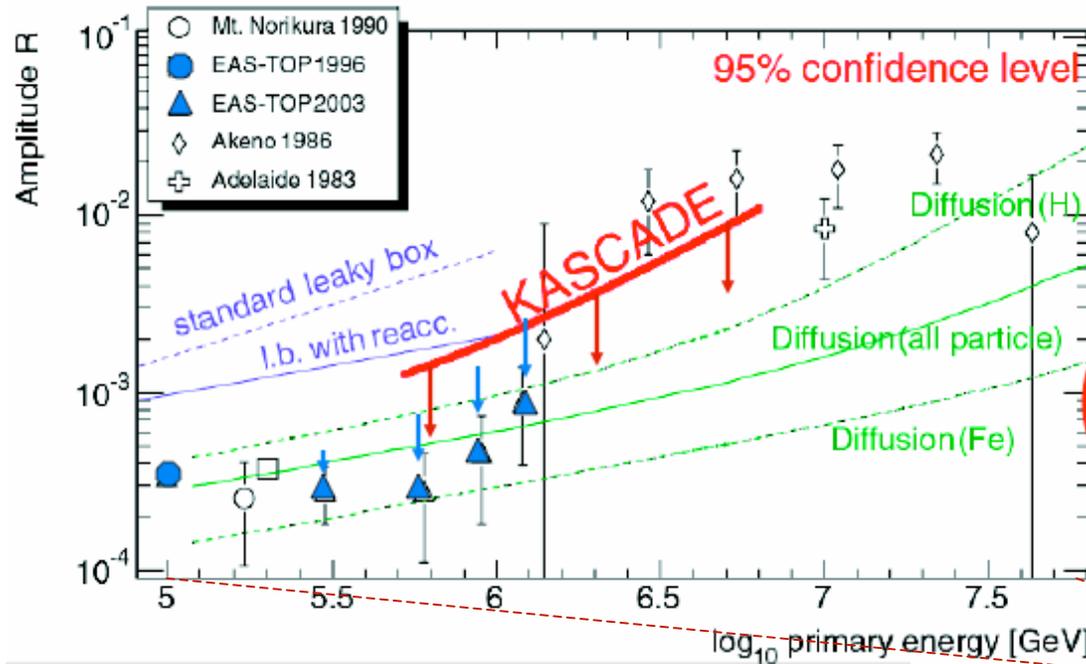

All data on sidereal anisotropy show good consistency up to 100 TeV

They are consistent with large scale diffusive propagation in the Galaxy

Solar wind effects

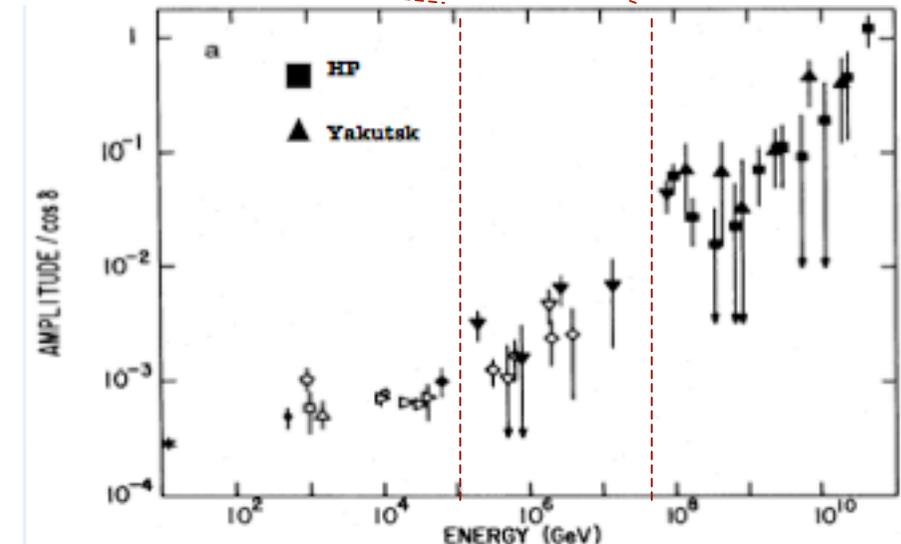

The high energy range

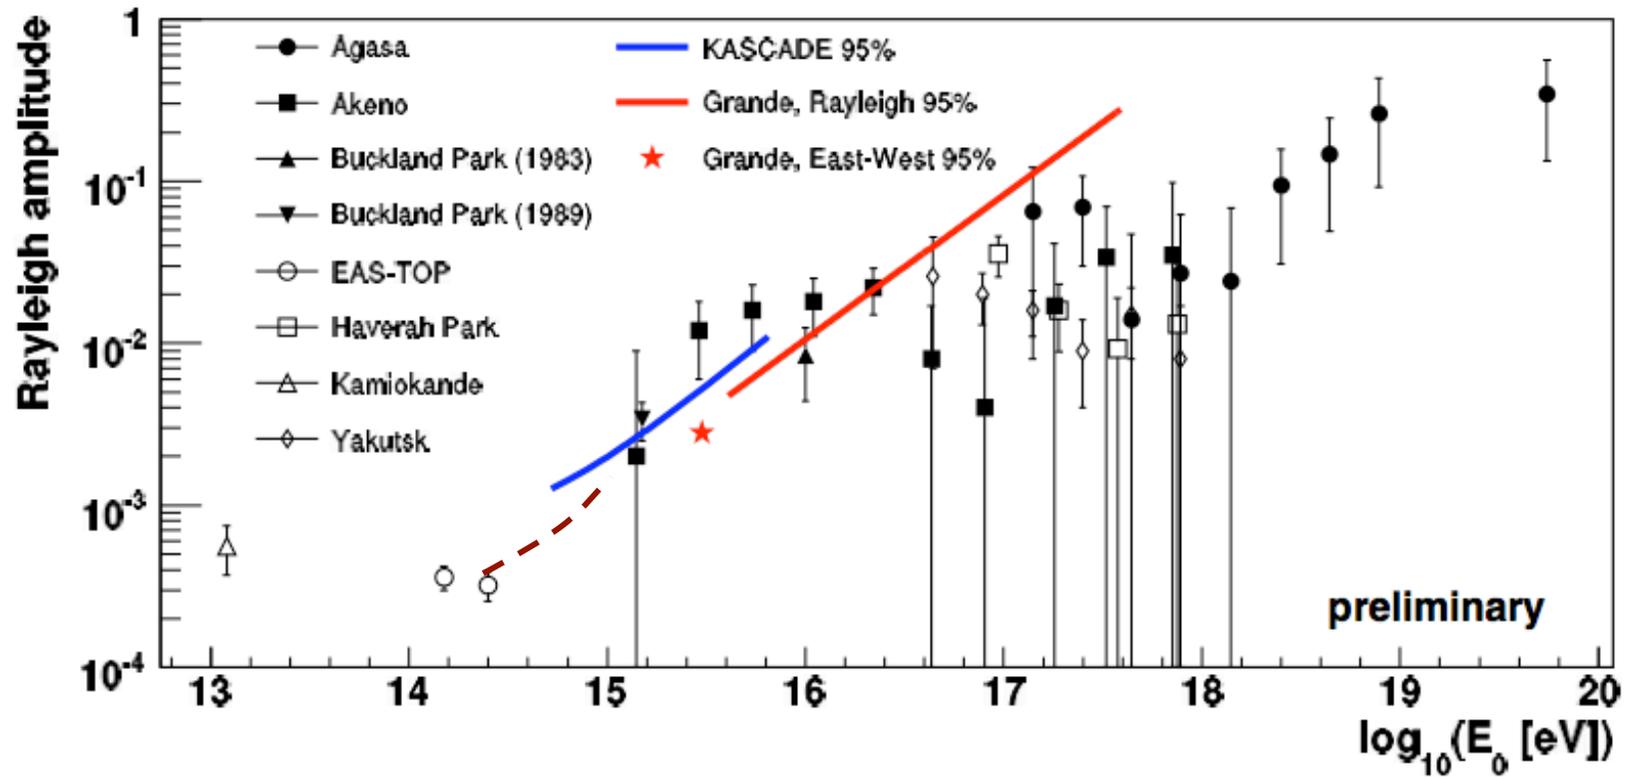

Old data seemed to suggest an increasing of amplitude
 ...but increasing amplitude where decreasing number of events!

Even for new results, data suffer from statistics and systematic uncertainties

[M.Aglietta et al.,
 T.Antoni et al.,Ap.J. 604 (2004) 687.]

**The Galactic
to Extragalactic transition**

Future projects

The existing data
4 different models
Energy and Composition constraints

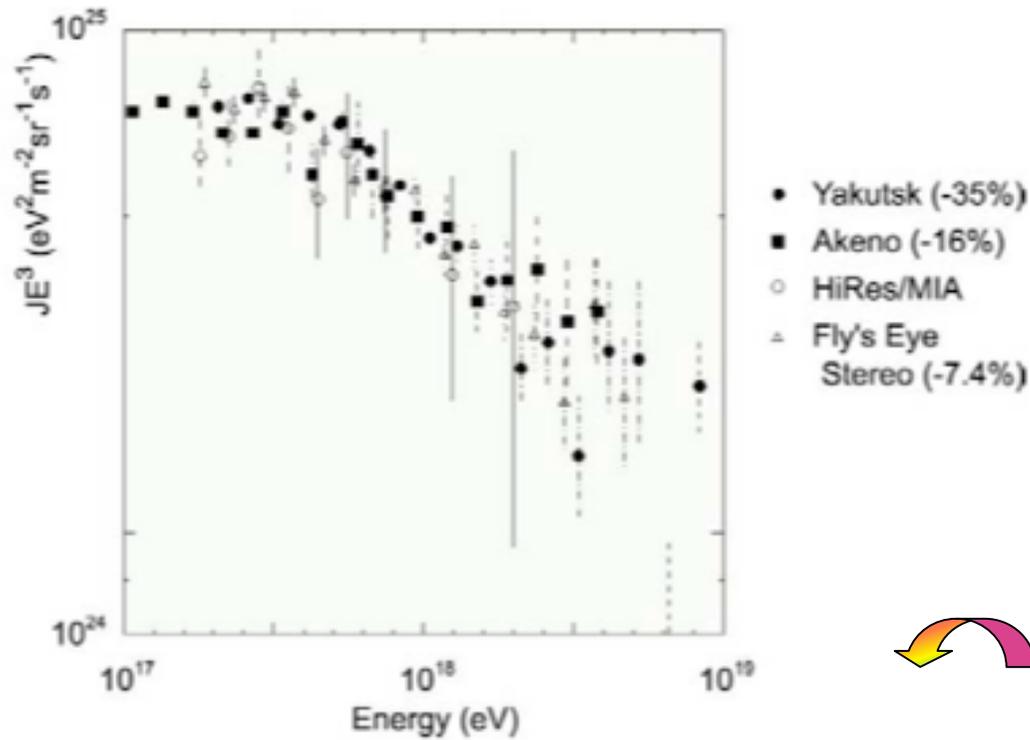

Second knee and ankle interpreted in

Ankle model [M.Hillas, J.Phys.G31 (2005) R95 and ref.therein]

Mixed composition model [D.Allard et al., Astrop.Phys.27 (2007) 61]

Dip model [V.Berezinsky et al., Phys.Rev.D74 (2006) 043005]

➡ Check with existing data !!!

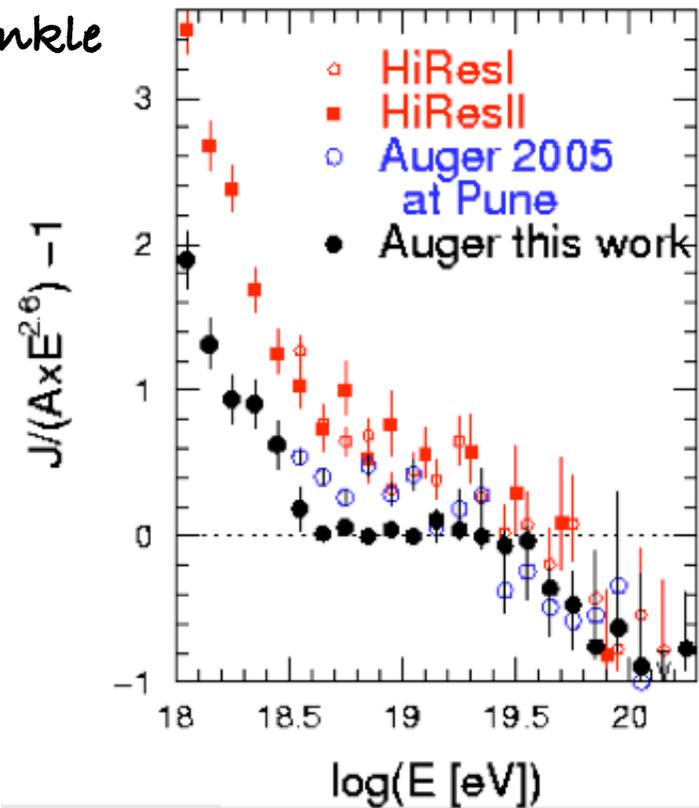

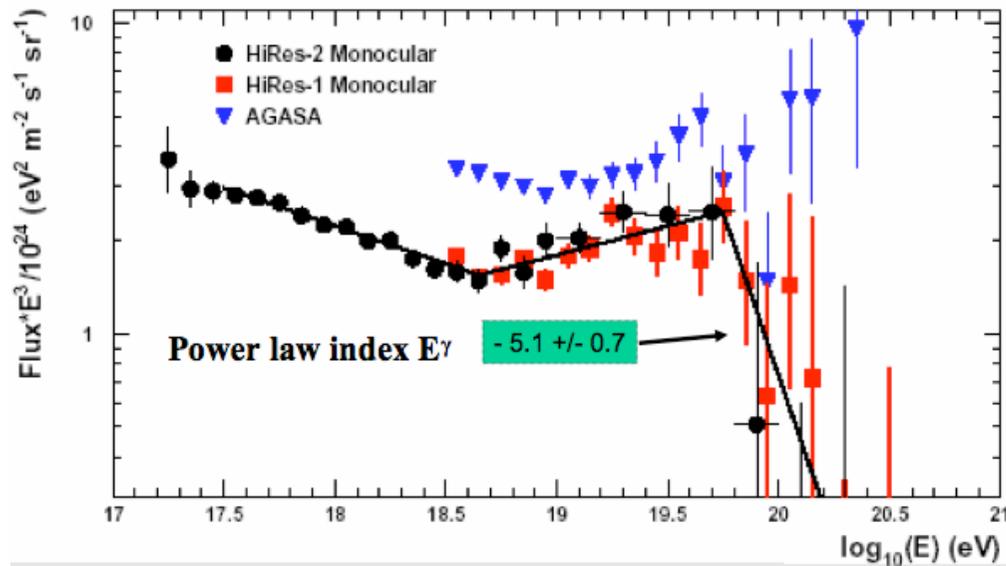

Existing data

Second knee

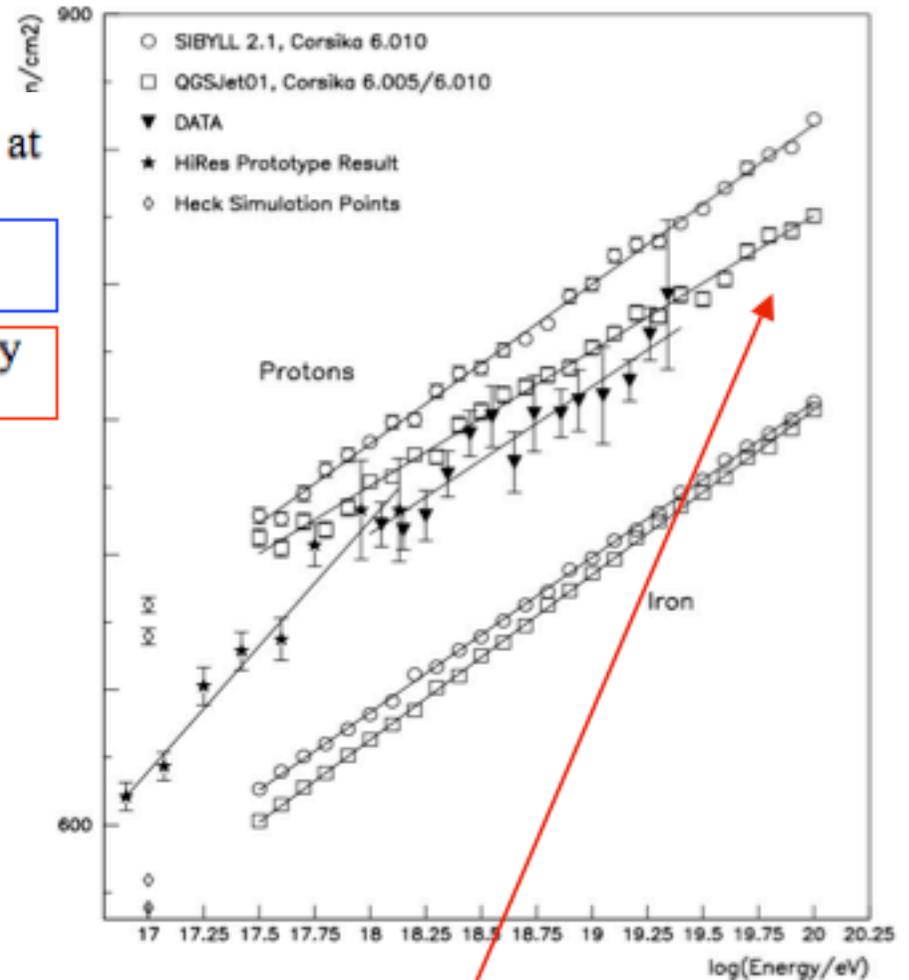

Ankle

HiRes Composition Measurement

- There is a **model-independent** break in slope at about 10^{18} eV.
- Heavy (galactic) nuclei decrease, give way to light (extragalactic) composition.
- Galactic/extragalactic transition is complete by about 10^{18} eV.
- Fits, plus QGSJet predictions, yield model of proton fraction as a function of energy.
- All fluorescence measurements of X_{\max} are consistent.
- Only fluorescence experiments SEE X_{\max} .

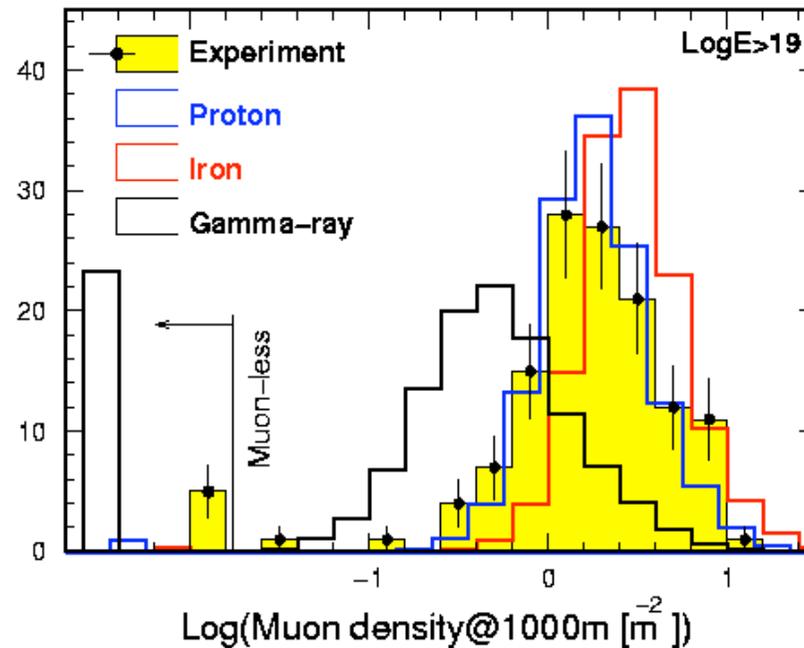

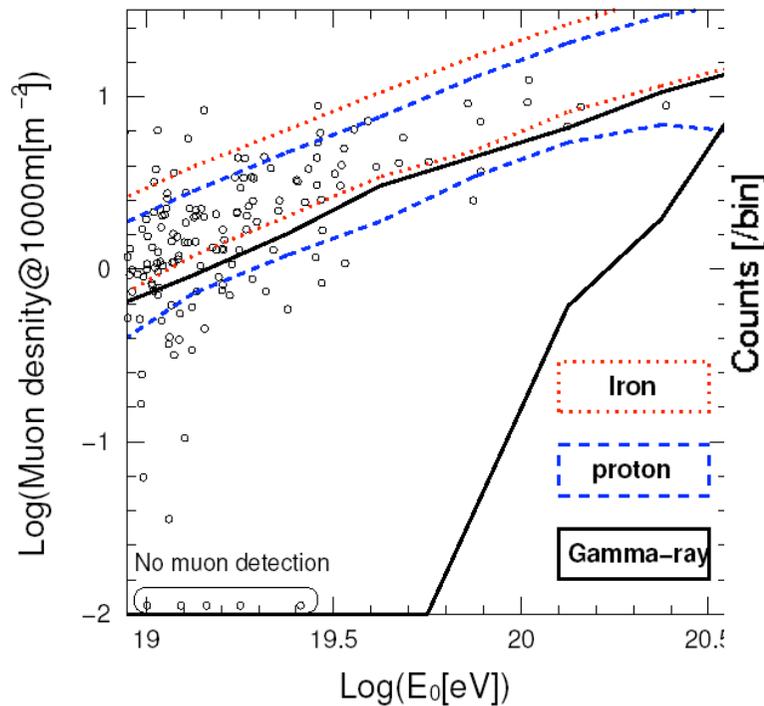

- **Higher statistics needed to extend analysis up to the GZK Threshold!**

The muon content from AGASA

Primary mass estimator: the muon density at 1 km $\rho_\mu(1000)$

Average relationship $\rho_\mu(1000)[m^{-2}] = (1.26 \pm 0.16)(E_0[eV]/10^{19})^{0.93 \pm 0.13}$

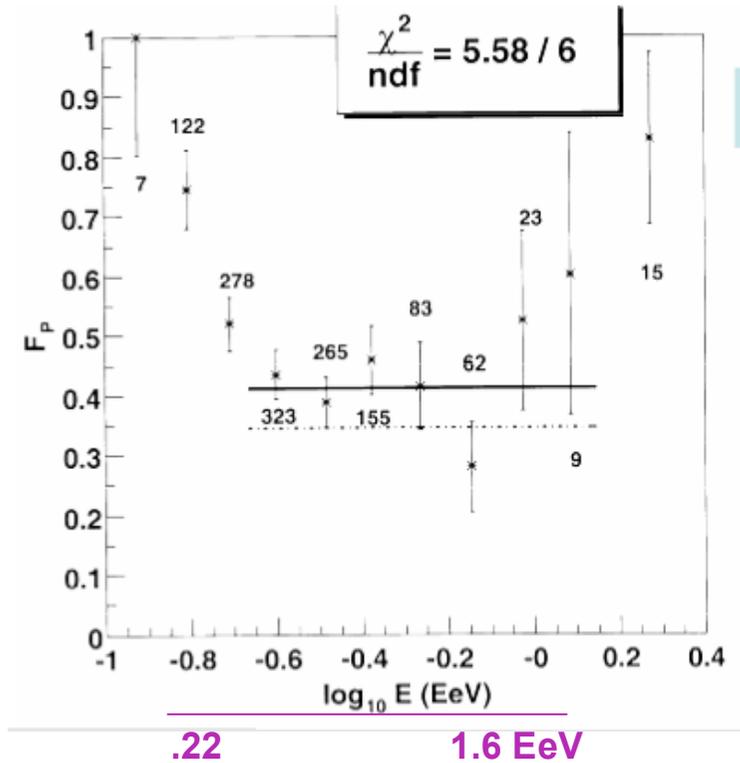

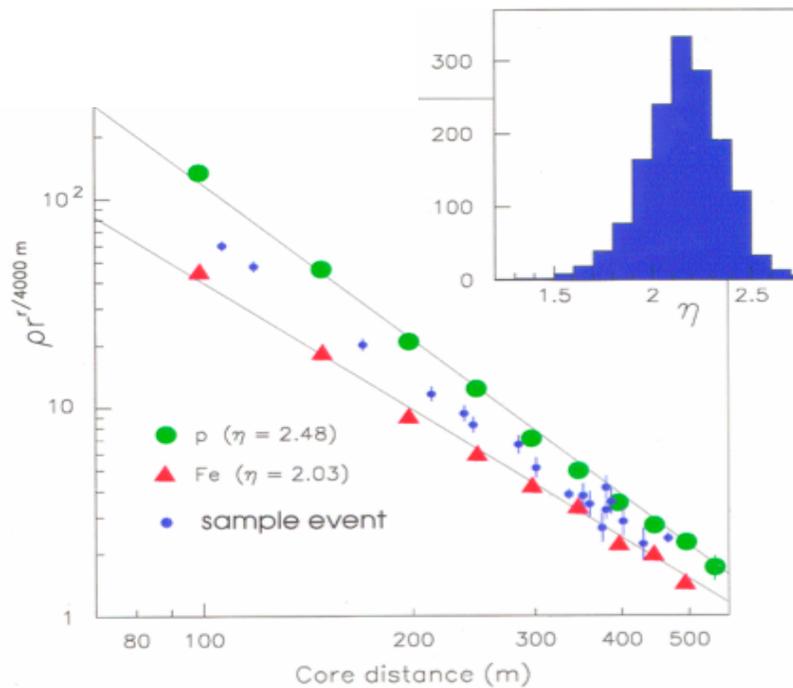

Gradual decrease of %Fe between $10^{17.5}$ & 10^{19} eV

Fe frac.: < 35% (10^{19} - $10^{19.5}$ eV)

< 76% (above $10^{19.5}$ eV)

The muon Ldf from Haverah Park

$$\rho_{\mu}(r) \sim r^{-(\eta+r/4000)}$$

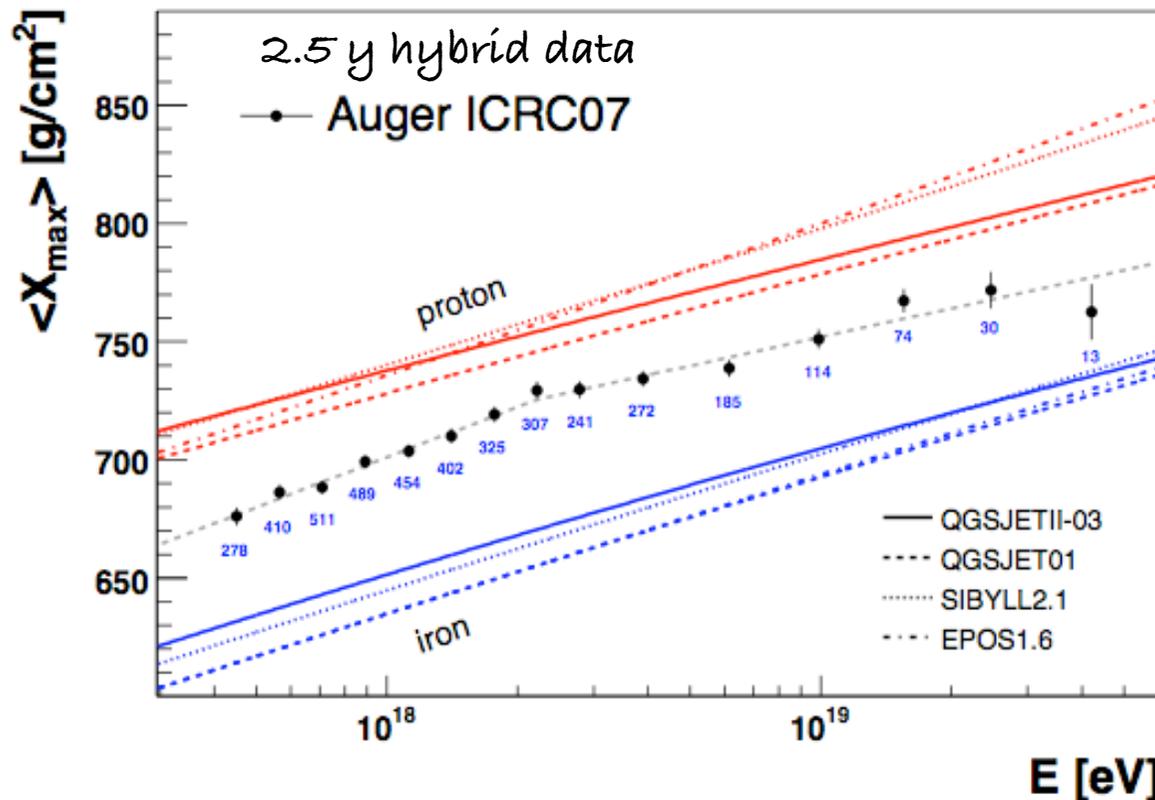

η = steeper for EAS developing later. Compare its spread with Expectations from different primary masses

LDF reanalyzed with recent models:
 Fraction of protons:
 $(34 \pm 2)\%$ with QGSJet98.
 Increase to 48% with QGSJet01.

The X_{\max} distribution from Auger

$$\langle X_{\max} \rangle = D_p [\ln(E/E_0) - \langle \ln A \rangle] + c_p,$$

D_p and c_p (average depth of a proton) depend on models

$$E_{\text{break}} \sim 10^{18.35} \text{ eV}$$

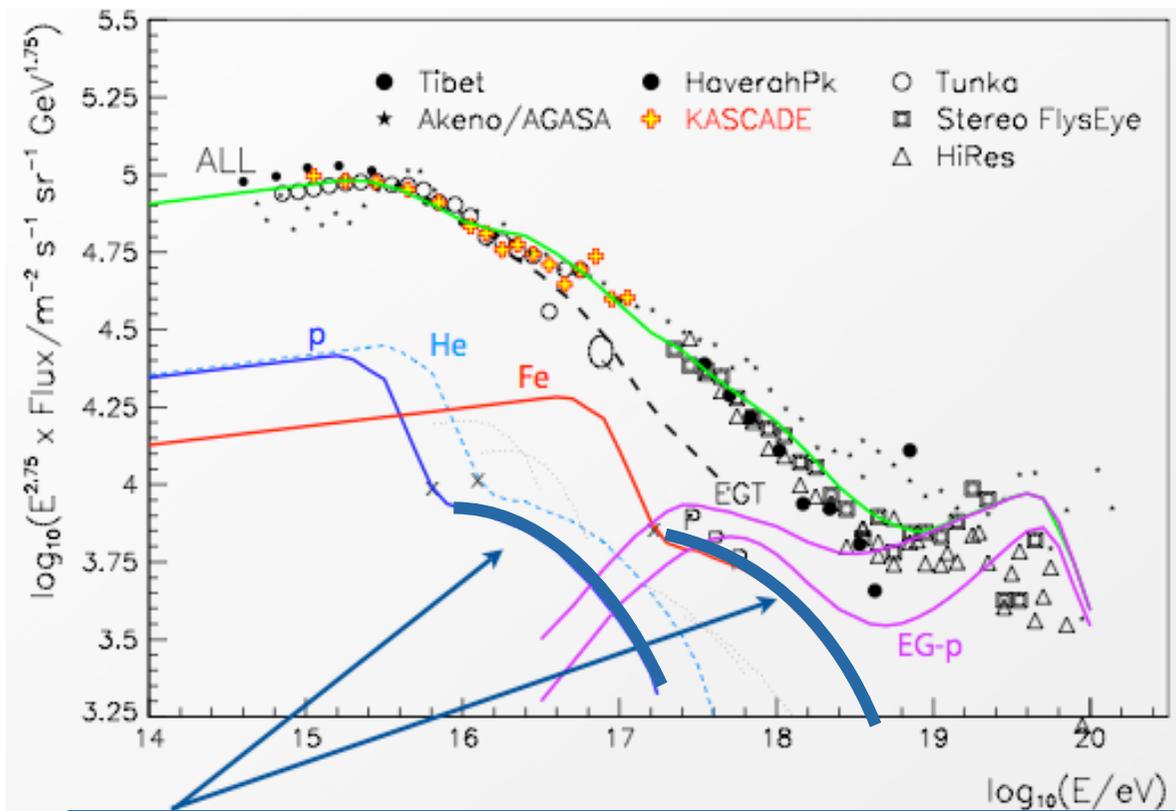

$$D_{10} = (71 \pm 5) \text{ g cm}^{-2} \text{ below}$$

$$D_{10} = (40 \pm 4) \text{ g cm}^{-2} \text{ above}$$

Result compatible with
Previous ones (but already
Better statistics!)

Systematics < 15 (11) g cm^{-2} atm + detector
22% uncertainty in FD energy scale

Ankle Model

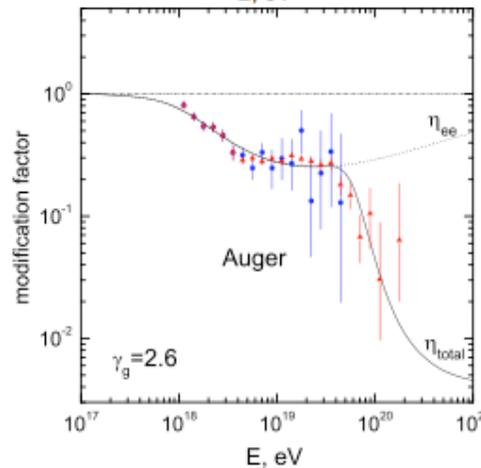

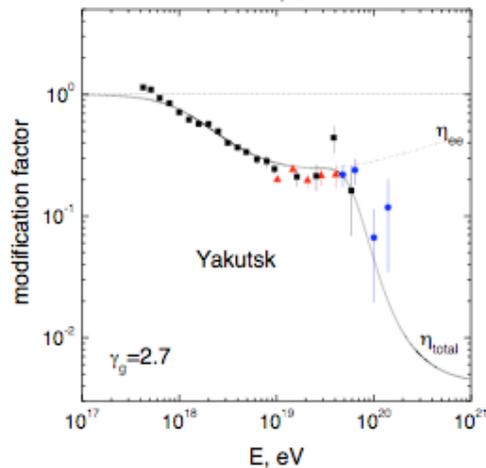

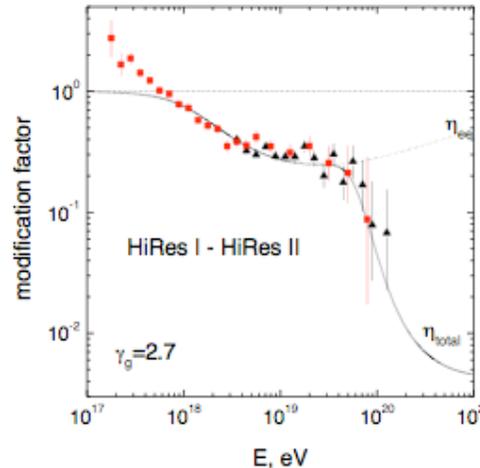

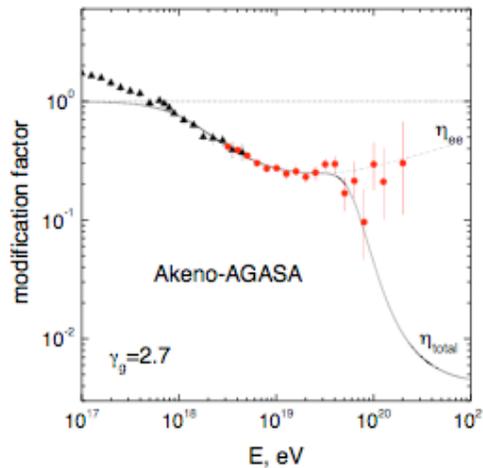

Needs additional component to link with SM
Galactic: modified DSAM with E_{MAX} 100 times >
 Bell-Lucek model: acceleration by type II SN
 whose precursor star emits a dense wind before
 explosion

- ☀️ GCR sum of all components with same rigidity
- ☀️ EGCR **protons** (+ some He)
- ☀️ Source spectrum $Q(E)$
 $\alpha=2.3$
 Similar to predictions from DSAM
- ☀️ **Transition at the ankle**
 Most natural shape of a transition

[M.Hillas, J.Phys.G31 (2005) R95 and ref.therein, I

Dip Model

- ☀ EGCR sources accelerate only **protons**
- ☀ Pair production dip in the propagated spectrum ($p + \gamma_{\text{CMB}} \rightarrow e^+e^-$)
The dip is seen by all experiments
Ankle is a natural feature included in the dip

- ☀ The GCR/EGCR transition occurs at the **second knee**
Very nice link to standard GCR model (transition close to $E_{\text{knee}}^{\text{Fe}}$)

... but

Source spectrum agrees with data if $Q(E) \propto E^{-\alpha}$ with $\alpha = 2.6-2.7$

Nuclei admixture $> 10-15\%$ destroys the agreement dip/data

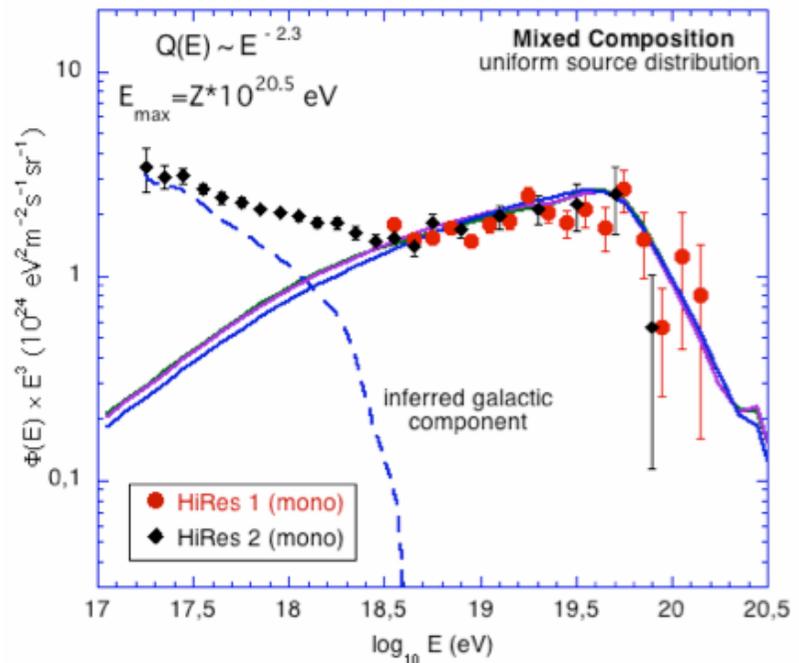

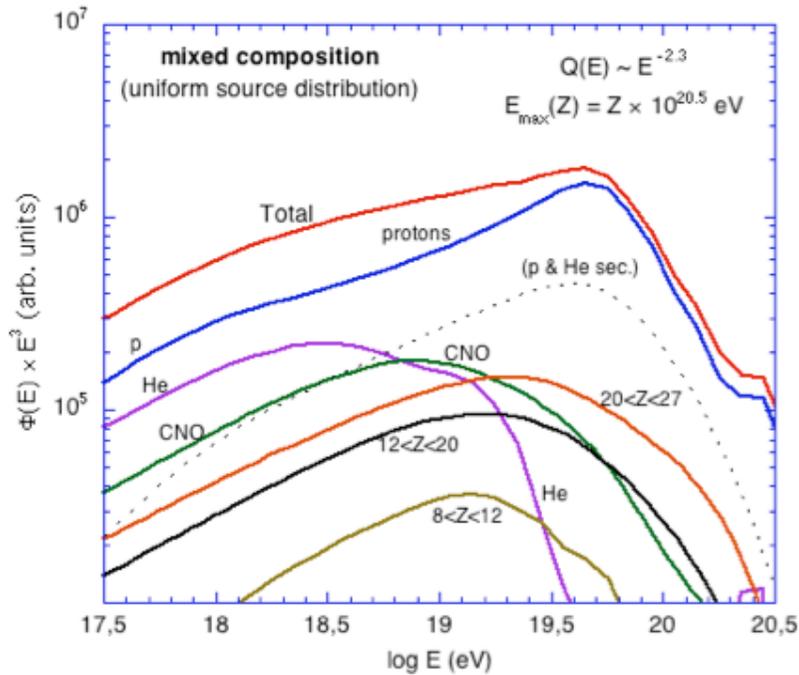

Modification factor:

$$\eta(E) = J_p(E) / J_p^{\text{unmod}}(E)$$

[V. Berezhinsky, 27th ICRC Conference, Merida (2007)]

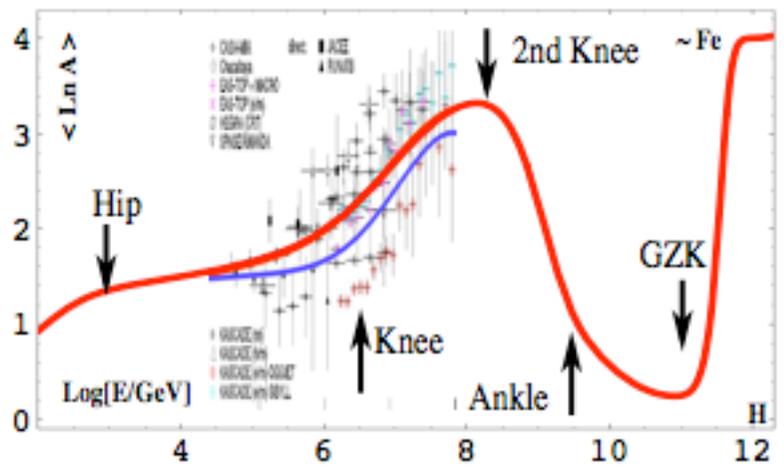

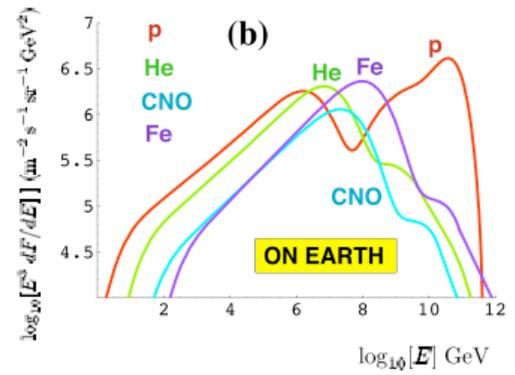

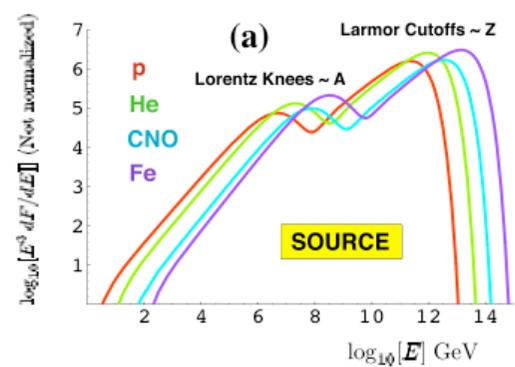

Mixed composition model

- ☀ Abundance ratios at source are similar to the GCR ones: **mixed composition**
 - ☀ Source spectrum $Q(E) \propto E^{-\alpha}$ adjusted to fit data: **$\alpha=2.3$**
Agreement with predictions from DSAM
 - ☀ **The ankle = end of GCR/EGCR transition**
 - ☀ The dip is filled by contribution of elements other than protons
 - ☀ The propagated spectra are not sensitive to a small change in composition (less He or more Fe)
- ...but injection spectrum $\propto A$?
composition?

[N.Globus et al., A&A 437 (2007) 1]

Cannonball model

CB of ordinary matter plasma is emitted when part of the accretion disk falls onto the compact object

$\gamma_{CB} \sim 10^3$ to agree with observations
 $E_{jet} \sim 1.5 \cdot 10^{51}$ erg (5 CB/jet)

Fluxes at 1st knee: $E_p \sim 4 \cdot 10^{15}$ eV,
 $E_A \sim A E_p$

Flux at 2nd knee: dominated by Galactic Fe

Extragalactic protons above 10^{19} eV.
 Acceleration stops when $r_L \sim r_{CB}$
 $(2-6) \cdot 10^{11} Z$ GeV

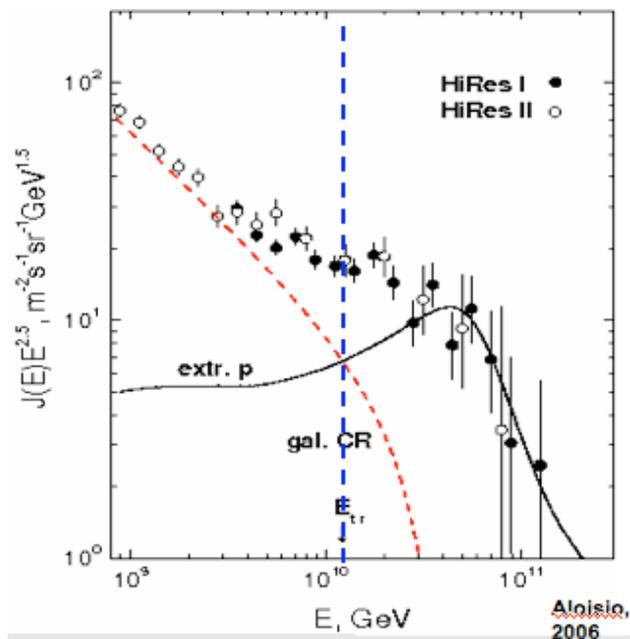

The expected X_{max} is intermediate between dip and mixed composition models

Transition in all models : a steep galactic spectrum intersecting a flatter extragalactic one

All models must explain the measured spectrum and composition and agree with the Standard Model of Galactic Cosmic Rays

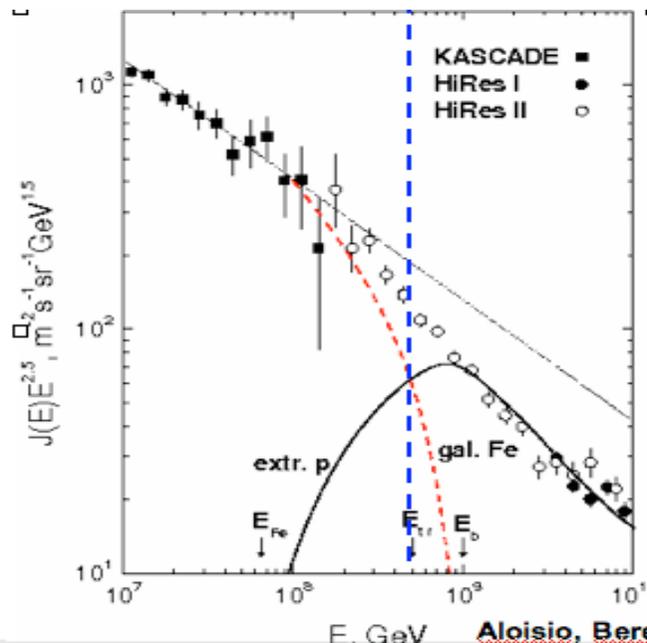

Ankle Model:

- Transition at ankle
- GCR > 10¹⁹ eV, Fe dominated.
- additional GCR needed
- p, can include heavy nuclei

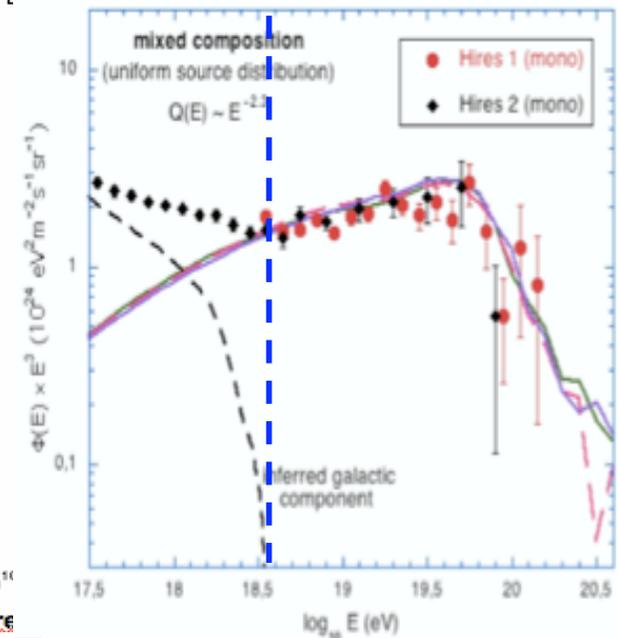

Dip model:

- Transition at second knee
- Ankle as part of the dip (p + $\gamma_{\text{CMB}} \rightarrow e^+e^-$)
- pure proton composition

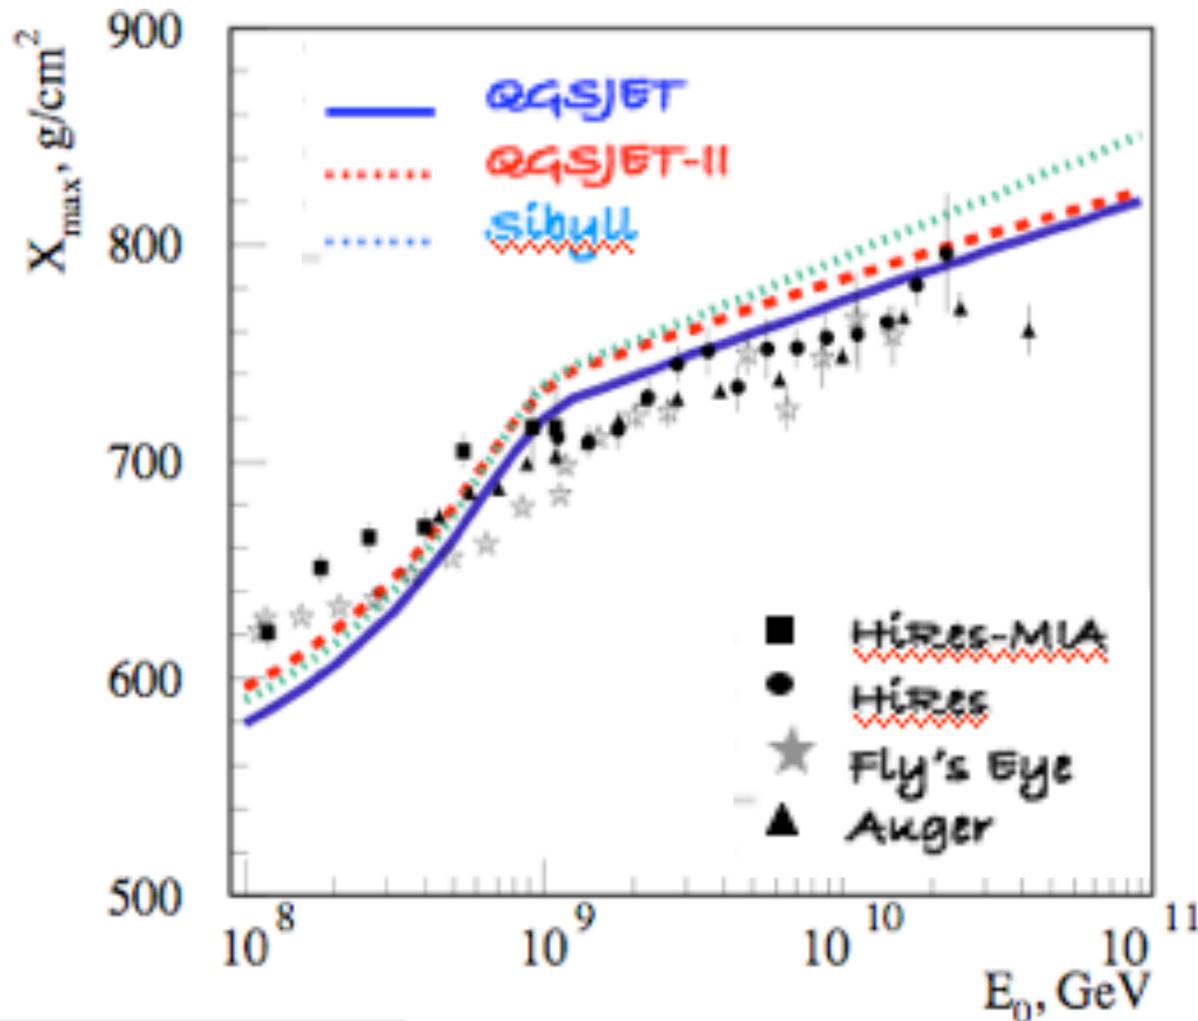

Mixed composition:

- Transition at ankle
- source spectrum as predicted by DSAM
- mixed composition

Before the transition → anisotropy is expected to increase ($r_L \sim$ galactic disk thickness)
 After the transition → large scale isotropy

Composition constraints

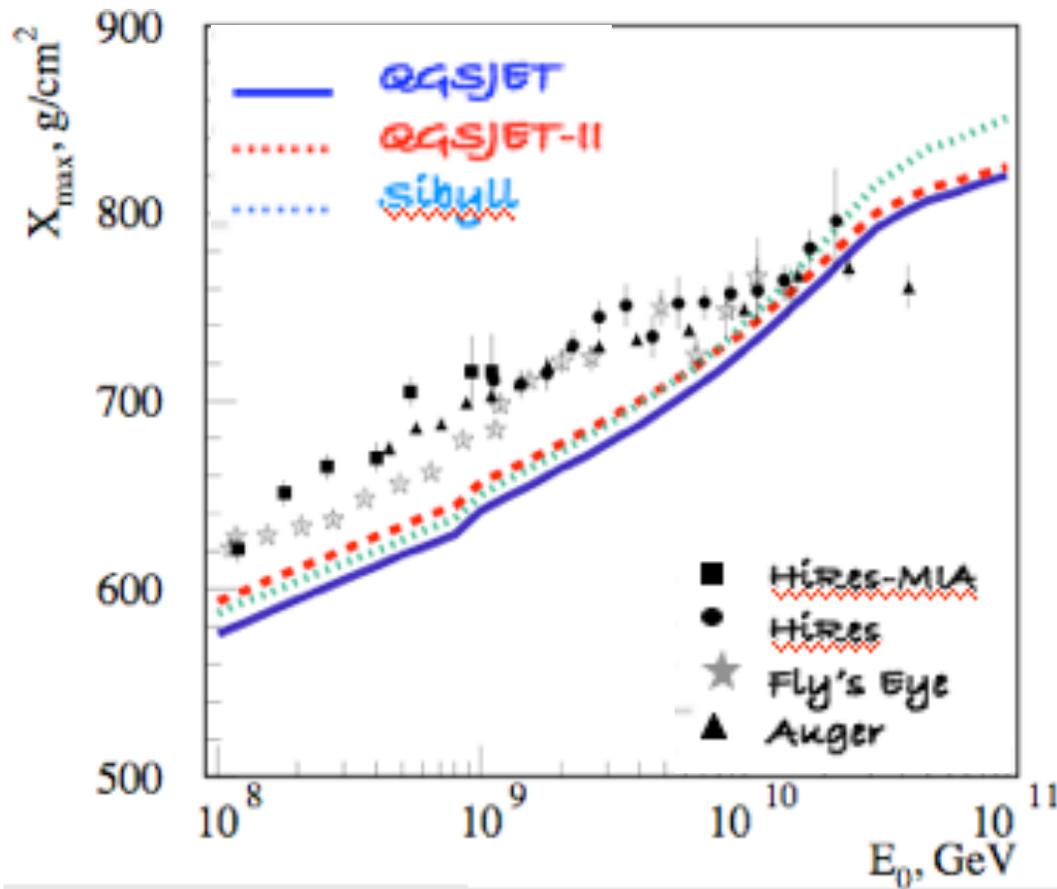

Dip-based model

Sharp rise $10^{17} - 10^{18}$ eV
due to sharp transition
from Galactic Iron to
extragalactic protons.

Systematic errors on
 $X_{\max} \sim 20-25 \text{ g cm}^{-2}$

Composition constraints

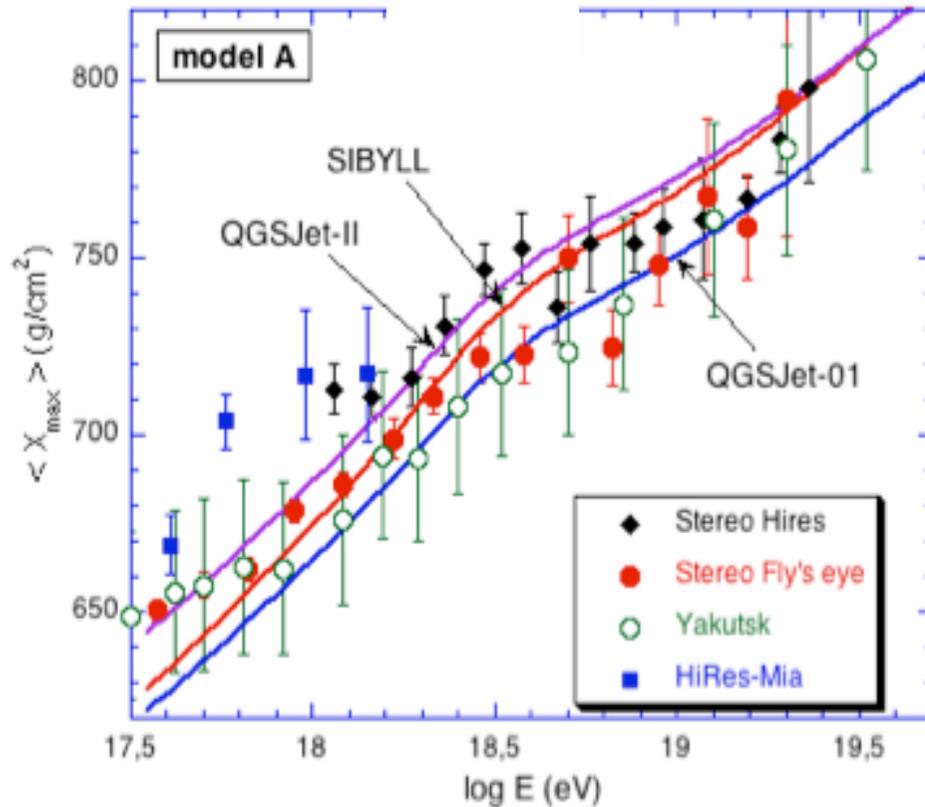

Ankle model

The transition is much smoother, the composition becomes proton-dominated only above 10^{19} eV.

Clear underestimation of X_{\max}

Composition constraints

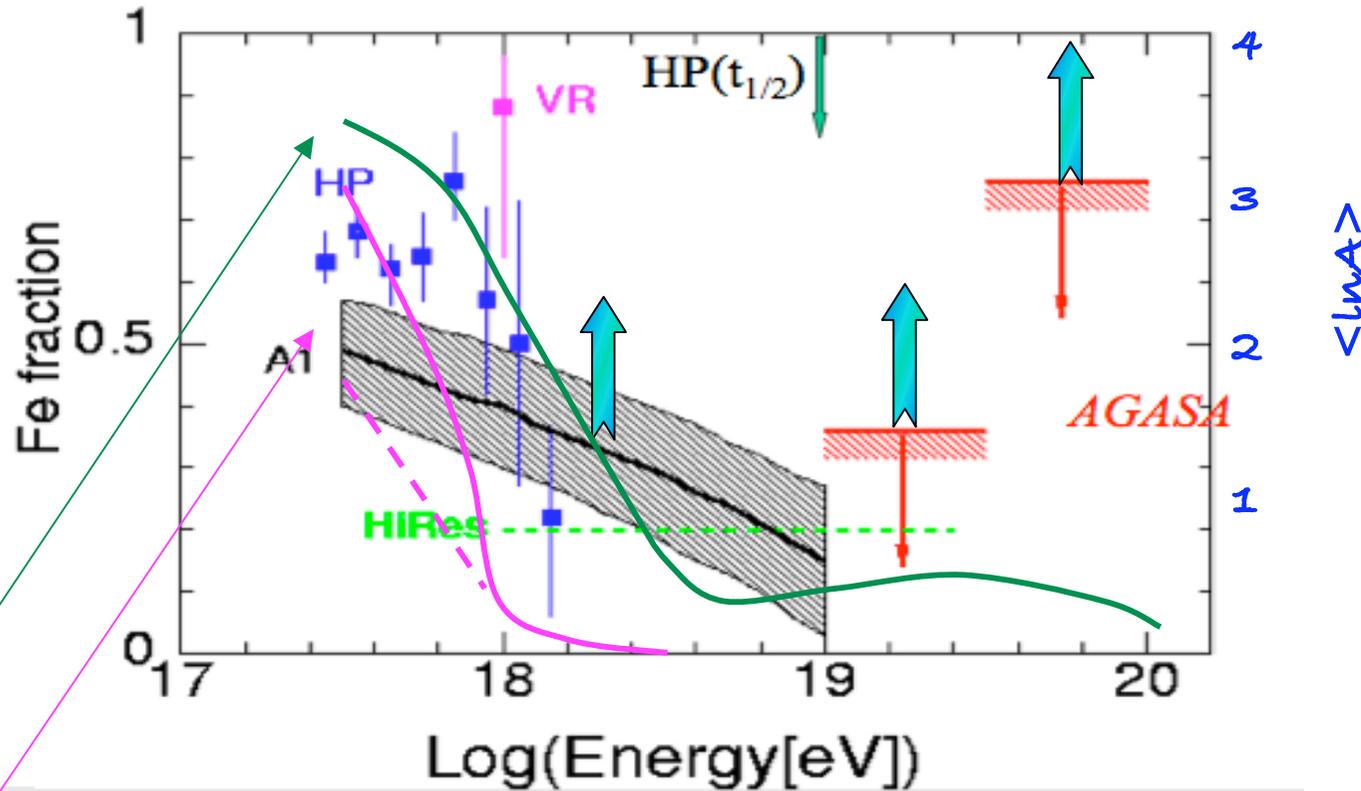

Mixed comp.model

Good fit of Fly's Eye and Yakutsk.

Differences within 20 g
 cm^{-2}

Composition constraints

(A) **Mixed comp.model** Fe very large up to $3 \cdot 10^{17}$ eV; >50% up to 10^{18} eV
 Significant fraction of Fe above 10^{18} eV

(B) **Dip based model** $\sim 45\%$ Fe and 55% p at $3 \cdot 10^{17}$ eV; $\sim 10\%$ Fe at 10^{18} eV
 (——— with harder spectrum $\propto E^{-2}$ below 10^{18} eV,
 - - - - with spectrum $\propto E^{-2.6}$ below 10^{18} eV)

Auger - HEAT

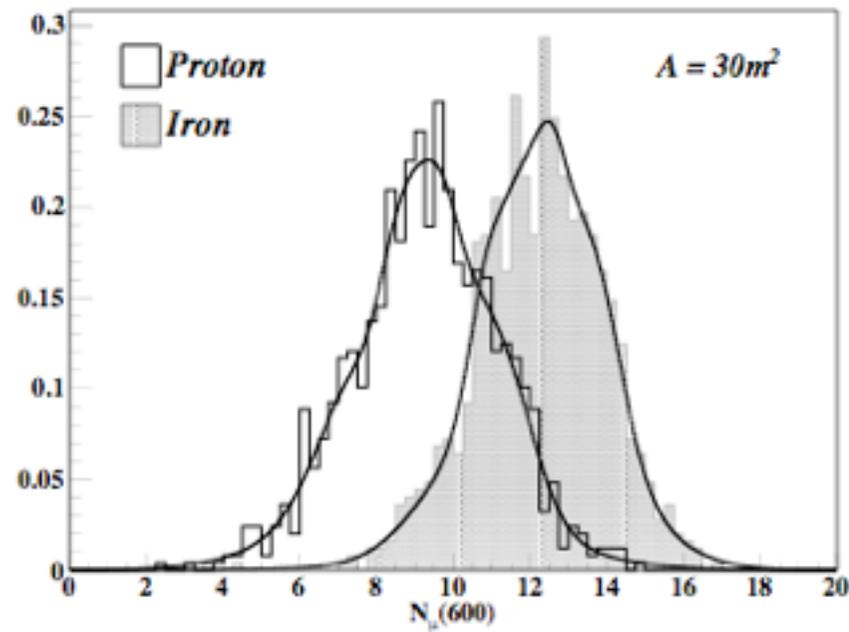

At low elevation field of view, the X_{max} of low energy EAS is seen only at large distance

Energy range widens down to 10^{17} eV

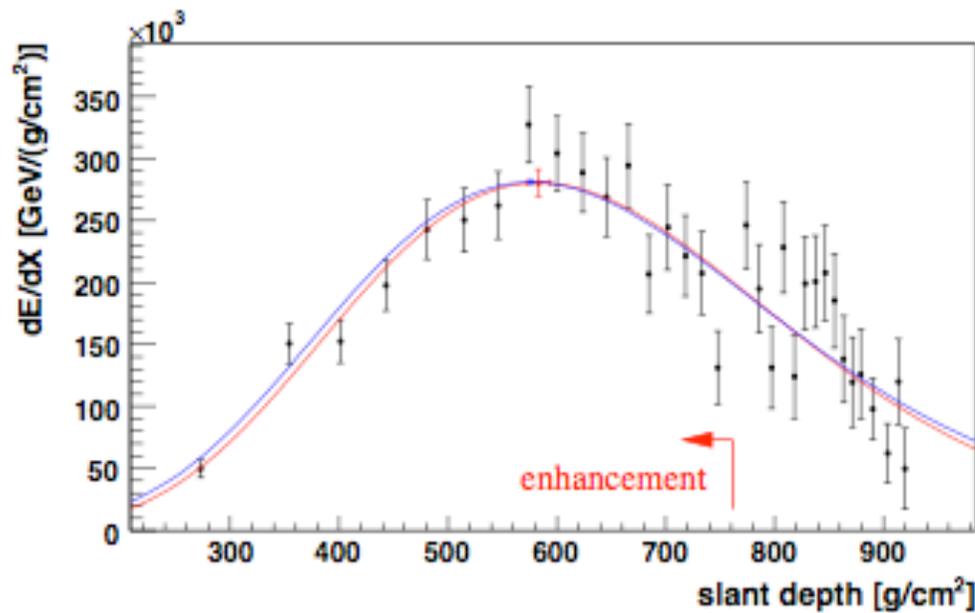

Hybrid mode HEAT/AMIGA: ~ 200 events/y $\sim 10^{18}$ eV

AMIGA

Simulation:

μ count rates at 10^{18} eV, 30°
 5000 events/year expected
 for $E > 10^{17.5}$ eV

HEAT

Simulation:

longitudinal profile of a shower

$E^{17.25}$ eV, core distance 1.2 km

Summary on the transition region

The transition region is of the utmost importance to understand the global picture of origin, acceleration and propagation of GCR + EGCRs

Different models can be distinguished using their prediction on composition, spectral shape and anisotropy

The present HiRes X_{max} results seem to confirm the proton-dominant composition expected in the frame of the dip model. Auger data are in agreement within errors.

All 3 models need adjustment to match the Galactic spectrum, but some ways out can be found

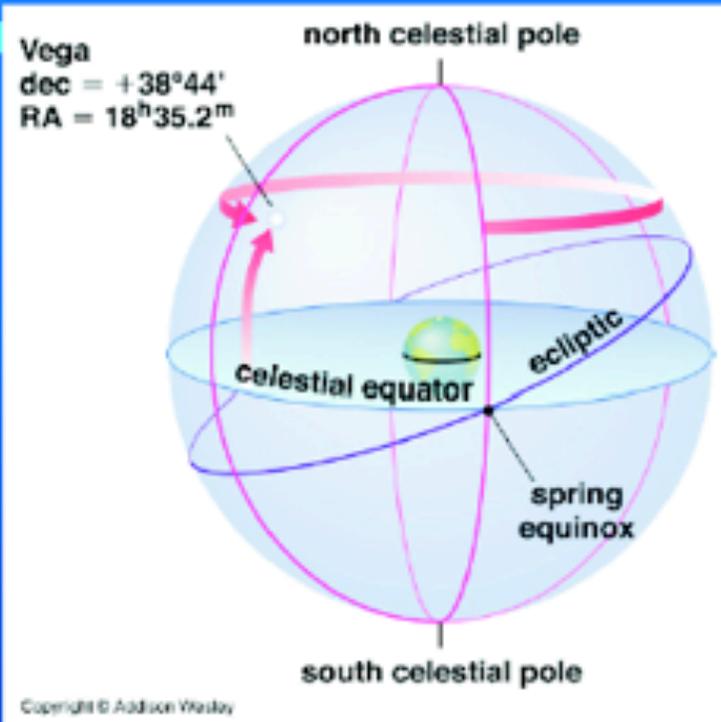

Future projects, first KASCADE-Grande and TALE, and in the future the Auger low energy enhancements, will give us a powerful tool to clarify the problem

THE END ?

....of course NOT !!!

Right ascension and declination

A sidereal day (time the Earth takes to rotate once wrt to the stars) lasts 23h 56'

Declination δ

$$S_D = \sin \delta_L \cos \vartheta + \cos \delta_L \sin \vartheta \sin \varphi$$

$$C_D = (1 - S_D^2)^{1/2}$$

$$\delta = \tan^{-1} \frac{S_D}{C_D} \quad \delta_l = \text{latitude of the array}$$

Right ascension r.a.

$$S_H = -\cos \varphi$$

$$C_H = -\sin \varphi \sin \delta_L + \tan \vartheta \cos \delta_L$$

$$r.a. = t_s - \tan^{-1} \frac{S_H}{C_H} \quad t_s = \text{local sidereal time}$$

r.a. is measured in units of sidereal time

The Fourier analysis:

A serie of experimental data $x(t)$ measured in the time interval T

$$x(t) = \frac{a_0}{2} + \sum_{1 \leq k \leq \infty} \left(a_k \cos \frac{2\pi kt}{T} + b_k \sin \frac{2\pi kt}{T} \right)$$

$$x(t) = \frac{a_0}{2} + r_1 \sin \left(\frac{2\pi t}{T} + \varphi_1 \right) + \dots + r_k \sin \left(\frac{2\pi kt}{T} + \varphi_k \right) + \dots$$

And for identical dt :

$$a_k = \frac{2}{N} \sum_{1 \leq i \leq N} x_i \cos \frac{2ki\pi}{N} \quad b_k = \frac{2}{N} \sum_{1 \leq i \leq N} x_i \sin \frac{2ki\pi}{N}$$

$$r_k = \sqrt{a_k^2 + b_k^2} \quad \tan \varphi_k = \frac{a_k}{b_k}$$

Amplitude and phase of the k -th harmonic

The Rayleigh formula

If a first harmonic amplitude $r \neq 0$ is detected, the probability of it being the result of a fluctuation in an isotropic distribution is (for N data points)

$$P(> r) = \exp \left(\frac{-r^2 N}{4} \right)$$

with a significance

$$k = \frac{r^2 N}{4}$$

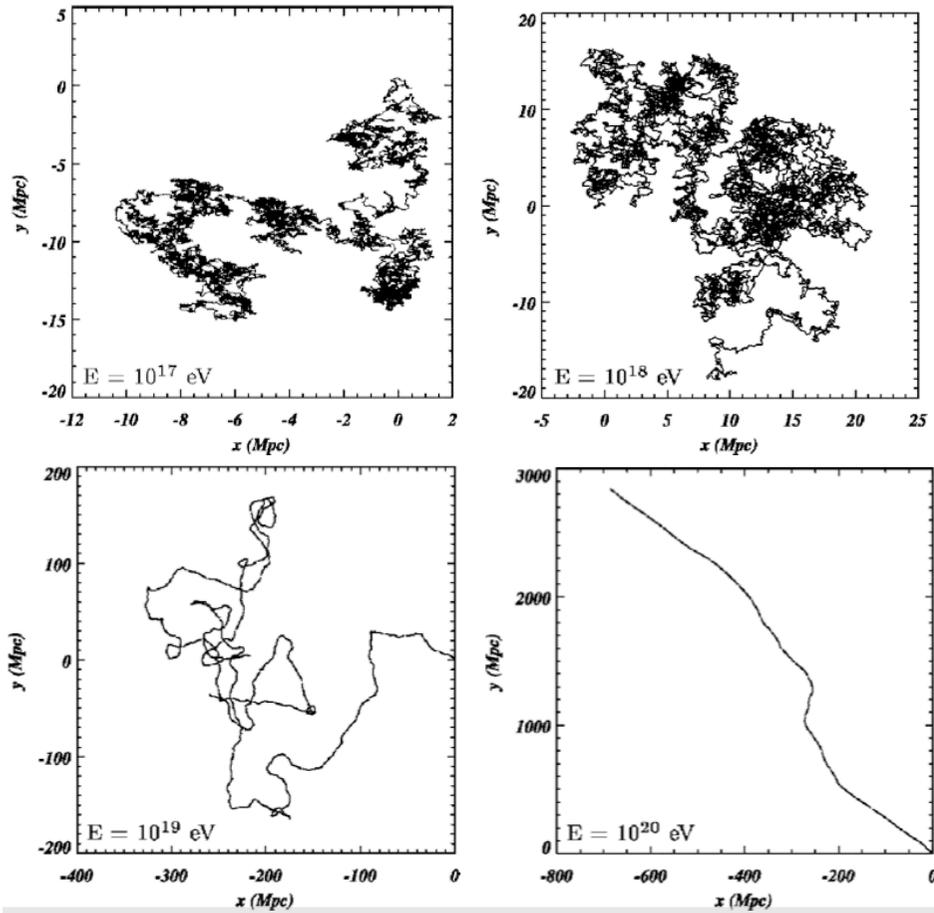

The EG magnetic field

EGMF poorly constrained
Current upper limits: $< \text{few nG}$

Individual trajectories depend only
on $r_g \sim 1.1 \text{ Mpc } E_{\text{EeV}} / Z B_{\text{nG}}$

➤ **Ballistic regime:**
deflections small,
distance from source $d \sim ct$

➤ **Diffusive regime:**
Isotropized particles undergo
diffusive propagation, $d \sim \sqrt{Dt}$

Magnetic horizon = maximum distance CR travel away from their source in a MF

$$R_{\text{magn}}(E) \approx \sqrt{4D(E) \min(\tau_{90}, t_s)}$$

At "low" energies (10^{17} - 10^{18} eV) possible suppression of the flux !
